Executive Summary

Projections prepared for Lancaster County show that the growth of the population and households will continue between 2010 and 2040 as it has every decade since 1900. Based upon three separate but related models, the total population increases rapidly from 54 to 77 percent from 2000 to 2040, with an increase of 65 percent to more than 410,000 persons as determined by the “trend” model deemed most likely to occur.

The three models depict scenarios regarding varying levels of migration. A “low series” model portrays future growth if net person movement resembles the relatively low levels that occurred in the county in the 1980s, a “high series” model depicts growth based upon the relatively high net migration of the 1990s, while the trend model shows growth if the longer term trend since the 1970s unfolds in the future. The models illustrate population change based on decade migration rates of 2.0, 5.5, and 9.0 percent for the low, trend, and high series respectively.

Utilizing Census 2000 data by single years of age as a starting point, the models “flow through” the population cohorts based upon age-specific migration rates, localized birth rates by age of the mother, and single year of age survival rates. Analyzing by single years of age is critical for Lancaster County given the “jumps” in migration that occur as college students move into and out of the area. Detailed local analyses regarding the college-aged population structure and its corresponding migration are key components and a strength of these projections, which likely differentiate the values from these models from others that are available.

The models show that growth will occur among all major age groups, with the highest percentage gains among the 65 and over population, as persons born in the “baby boom” of the 1950s age into this cohort. The models are quite uniform in depicting how the population will change over time, with the primary difference between them being the level of the overall population given varied migration. Numerous graphs and charts in the report illustrate the specifics of how the overall population and age structure will change, as influenced by vital events such as rising levels of both births and deaths within the county.

The projected population from the trend model is the basis for projecting how the household structure will change. Calculations projecting the distribution of the population between households and group quarters function to determine that the number of households will increase to more than 165,000 by 2040. The percentage of one-person households will continue to increase, representing 36 percent of all households in 2040, a gain of five percentage points compared to 2010. Long standing trends of family households and those with children declining as a relative share of all households are assumed to continue into the future.

These projections aid in the planning and decision-making process regarding how to adapt to the coming changes in the population’s structure. While no projection can be exactly accurate and future local or world events can change population dynamics quickly, projections can be used as a guide for understanding the changes that are likely to occur. Area leaders can utilize this information to prepare for Lancaster County’s continued growth which will continue unabated for the foreseeable future, as positive population fundamentals such as births steadily exceeding deaths and anticipated net immigration occurs.

Discussion

The populations of Lancaster County and the city of Lincoln have been growing. This growth has not just occurred recently, but in every decade since 1900, even managing a small gain in the depression years of the 1930s. In more recent times, population growth has achieved a high decade rate above 17 percent in the 1990s, a low decade rate slightly above 10 percent in the 1980s, with the 1970s and post 2000 period falling in the middle of this range, with growth rates of about 14 percent.

Will the local population grow each decade in the near future? What rate of growth is most likely? Will increases occur primarily in certain age groups? How will the number of households and average household size change? These are the types of questions that population projections can provide insight on. No one knows exactly how population changes will occur, and unforeseen future local and world events such as recessions or wars can change population dynamics dramatically. In general, however, mathematical modeling based on the past and utilizing assumptions for the future provides a sense of where the population of a place such as Lancaster County is headed.

Population projections are especially important as preparations continue for the needs of the sizable baby-boom population. With the first “boomers” turning age 65 in 2010, their changing needs given housing preferences, greater possibilities of losing a spouse, and eventual possible need for long-term care or nursing home facilities come into focus as one looks into the future to 2040. Current and future development of housing and infrastructure will need to adapt and prepare for the coming demographic changes. Population and housing projections can be a useful tool in the planning process.

Lancaster County has additional complexities regarding its population since several universities, a penitentiary, and Nebraska’s state government are located there. As such, Lancaster County experiences a relatively high rate of migration, attracting college-aged students and some in their early working years but also often has those with a newly completed degree move out of the area. Migration not only has a direct influence on individuals but also upon their immediate current family and more importantly their potential future family (eventual spouses and children). Thus, understanding and modeling migration accurately is a key component in portraying the future population structure of Lancaster County.

With migration in mind, these projections provide three separate models to illustrate various scenarios regarding the effect on population from differing levels of migration. With birth and survival rates remaining relatively steady over time, changes in migration are a more variable factor for how the population will change. This has been witnessed locally when lower levels of migration lead to lower growth rates in the 1980s, while the 1990s had relatively high levels of migration and growth. Therefore, the varying series illustrate a conservative approach to growth based on low migration rates from the 1980s, an aggressive growth scenario using high migration rates from the 1990s and a trend model which can be viewed not only as an average between the high and low levels but also indicative of the longer term trend since 1970 and extending into the post 2000 period.

The trend level of migration and growth is the scenario we assume is most likely to occur, as it smoothes the actual future changes that will likely sometimes be above and sometimes below the trend level. The trend level of growth is believed to be the most reasonable for evaluating longer periods of time, as Lancaster County has not experienced consecutive decades of either high or low growth in recent times. Therefore, the low and high series are based upon such migration rates for the 2005 to 2020 period and then gradually return to the trend level of migration by 2040.

Migration rates during the 1980s, 1990s, and 2000s period as illustrated by the Census Bureau's intercensal estimates program were meticulously analyzed. Through this examination migration rates for five-year age groups were prepared and developed into rates for individual ages. Having rates by single years of age was crucial to correctly pattern the migration "jumps" that occur as college students both come into and often later leave Lancaster County.

A comprehensive analysis of how the population is structured for college ages was conducted and improved the overall precision of these projections by age. The detailed patterning of college ages and the age-specific migration rates are considered a strength of these projections when compared to others. Since these projections were tailored to Lancaster County specifically and updated and prepared using the most current data available, they provide a locally grounded approach to detailing the complex nature of Lancaster County's population.

Based upon the trend level of growth, the projections also provide information on the future housing structure in Lancaster County. These projections detail not only the total number of persons, but those living in housing units and group settings. With this information, the total number of households and average household size were determined, along with projections by age of the householder. Additionally, the number of one-person households and the number of nonfamily and family households, including those that have children under age 18, illustrate further details on the future housing structure. Such projections further aid planning and development regarding the demand for 1-person households (apartments and smaller homes) as well as housing and other amenities for families with children (parks, playgrounds, etc.).

While users of data from projections should exercise some discretion in the conclusions they draw from the information, the following points are viewed as some of the key pieces of information gleaned from the projection models. They are not necessarily listed in any particular order. Figures from the trend model will be cited the most frequently, since it portrays the scenario most likely to occur.

1. Based on the current 2009 population estimates from the U.S. Census Bureau, another year of growth typical for the 2000s period would give Lancaster County about 285,000 people in 2010. However, growth has probably been a bit stronger than normal lately, as Nebraska and Lancaster County have benefitted from increased migration from other parts of the United States harder hit by the housing and economic downturns (e.g. Florida, Arizona, Michigan, Ohio). So 286,000 to 288,000 persons is quite plausible, under the assumption that the estimates program has been fairly accurate in tracking the area's population since 2000. The trend model puts the 2010 population at 286,955, which seems reasonable (Tables 2 and 4).

2. The trend model pegs the 2040 population at nearly 413,000, a growth of more than 162,000 persons from 2000 or about 65 percent (Table 5). Both the low and high series differ from the trend model by 7 percent. Thus, the low series differs from the high series by about 58,000 people or 15 percent in 2040. Growth rates between 2000 and 2040 range from about 54 percent in the low model to 77 percent in the high model (Table 5).
3. While natural change will be a larger contributor to population growth in each five-year period than net migration, the relative difference between these two factors will shrink over time (Figure 1). Natural change has a relative uptrend until 2020, at which time it steadily decreases as the number of deaths increases relatively faster than the number of births beyond 2020 (Table 2). While the level of natural change declines slightly from its peak, it is a stable factor that contributes positively to population growth in all time periods.
4. The trend model's number of births increases more rapidly in the early and last portions of the projection period. Projected and actual births showed large increases between 2000 and 2005 (Figures 2 and 28). Births then increase more steadily until 2025, followed by another sharper uptick (Figure 2). Thus, it appears that there may be an increased need for schools based on the growth in births between 2000 and 2010 (Figure 28), followed by a potential lull in new school needs before an increasing demand for school capacity begins in the late 2020s. Natural change rates, driven largely by increased births in the 2000s, are the highest in Lancaster County in the 2000s decade since the "baby boom" ended in the 1960s (Figure 24) and the annual number of births is approaching the levels at the height of the baby boom (Figure 28).
5. The level of net migration in the trend model increases in all but one five-year period during the projection period (Table 2, Figure 1). Net migration, when broken into domestic and international components, shows that international migration, based largely on national projections customized to represent Lancaster County, increases steadily in a linear fashion (Figure 3). Domestic and total migration stem more directly from the relative sizes of the age cohorts that move through the age stages that have relatively high migration rates.
6. The models show similar differentials between the low, trend, and high series for the under 18, 18 to 64, and total populations. Stated another way, the models show similar patterns of change over time, just at differing levels (Figures 4-6).
7. A narrow differential exists regarding the number of persons age 65 and over in the low and trend models (Figure 7). One reason for this is that older age groups are generally less likely to move. Additionally, past data showed those in their 60s leaving Lancaster County but net immigration occurred among 70 year-olds so the net migration among the 65 and over age group was not all that different from zero. The high model shows a 65 and over population that increases more rapidly after 2020. This stems from increased migration throughout the projection period for persons in their 40s (originally in 2000 and subsequently in later time periods) – the high model has net immigration for those aged 40-49 while the other models generally do not. Thus, although this population group grows rapidly in each model (between 168 and 223 percent—Table 5), the ultimate level will be determined not only by survival rates and the actual migration of those 65 and over, but migration of those approaching their retirement years as well.

8. Given Lancaster County's migration structure where a large immigration occurs among college-aged persons followed by a general outmigration of those aged 25-34, increased levels of net migration lead to a sizeable increase in births and the under 18 population. The demographic theory of more positive migration leading not only to more people overall but also a higher level of children is especially apparent in Lancaster County. Retaining more persons in their 20s or 30s would have significant impacts on the population's overall structure.
9. Population pyramids show that the population aged 20-24 will maintain a relatively high portion of the total population for both males and females, as was the case in 1990 and 2000 (Figures 12-17). The color coding of the pyramids indicates the ages of those born during the depression, baby boom, and subsequent baby boom echoes over time and how their respective population percentages will change (e.g. 85 and older representing about 1 percent of the population in 1990 versus more than 4 percent in 2040).
10. Growth in the household population appears linear in nature while the group quarters population increases slowly at first and then more quickly later from 2020 forward, likely due to increased need for nursing homes among the aging population (Figure 18).
11. The total number of households increases steadily in a linear pattern reaching more than 165,000 in 2040 (Figure 19, Table 6). While both family and nonfamily households increase in number, the projection shows the rate of growth will be faster among nonfamily households (Figure 19). Part of this is due to increases in 1-person households (nonfamily by definition), which are projected to increase about 5 percentage points from about 31% of all households in 2010 to 36% in 2040 (Table 6, Figure 22). Some of this change likely stems from married baby boom couples moving into age cohorts where the loss of a spouse occurs more frequently, thus changing from a 2-person to 1-person household.
12. While both family households and those with children will increase in overall number, their relative percentage or share of the total number of households will continue to decrease as it has tended to since 1970 (Table 6). An exception to this overall downtrend is occurring currently, but it is believed the longer term pattern will reemerge as the third wave of increased births stemming from the baby boom begins to subside.
13. The number of households with a householder aged 65-74 will double from 2010 to when it peaks in 2030, those with a 75-84 year-old householder will nearly triple by 2040, and those with a householder aged 85+ will more than triple by 2040 (Table 6, Figure 21). Younger age groups change largely due to the movement of the persons born about 1980 in the baby-boom echo and 3rd wave of higher births during 2000 and 2010 that stems from the original from the baby boom (Figure 20).

Graphs of Historical Lancaster County Data

These graphs help illustrate the history of Lancaster County regarding population change and its components, natural change and net migration. The graphs show some of the values and trends upon which the assumptions of these projections are based. They provide both the historical and current context for how the Lancaster County population has changed.

Figure 23: Lancaster County Population Change by Decade: 1910 to 2009

Source: US Census Bureau, Decennial Censuses and Annual Estimates (released 3-23-10)

Figure 24: Natural Change Rates for Lancaster County: 1950 to 2010

Sources: Decennial Censuses and Annual Estimates (released 3-23-10), U.S. Census Bureau; Vital Statistics Reports, NE Dept of Health & Human Services

Note: A positive natural change rate reflects having more births to area residents than deaths of area residents.

Figure 25: Net Migration Rates for Lancaster County: 1950 to 2010

Sources: Decennial Censuses and Annual Estimates (released 3-23-10), U.S. Census Bureau; Vital Statistics Reports, NE Dept of Health & Human Services

Note: A positive net migration rate is referred to as net immigration, where more people are moving into than out of an area; negative rates show net outmigration.

Figure 28: Lancaster County Births, Deaths, and Natural Change: 1946-2008

Methodology

The methods utilized in preparing the projected values varied by the type of data being projected and the amount of available historic and projected data for the United States and/or Lancaster County. The methods also varied between Phase I of the project (population projections) and Phase II (household projections). The following section details the methods used for each phase of the project.

Phase I – Population Projections

Age-Specific Migration Rates

A major piece of data impacting the projections was the determination of age specific migration rates. Given Lancaster County's structure as home to a major university, the county experiences a relatively high level of migration as many move to the county for college and often subsequently move away upon completion of a degree. Migration is not limited to college-age persons of course. Those of working age along with their families are moving into and out the area and many persons move upon entering retirement. Establishing these migration rates were a key part of the projections process.

In order to calculate the migration rates, we analyzed the “flow” of persons between the 10 year periods between 1980 and 1990 as well as 1990 to 2000. It was known that the county gained persons at a relatively low rate of 2.0 percent during the 1980s and a relatively high rate of around 9.0 percent in the 1990s. The average of these rates was about 5.5 percent and represented the “trend” level of migration. The trend value was also supported by estimates of migration in the post 2000s period released by the U.S. Census Bureau and the average longer term trend looking back to migration since 1970. What was not known was how the migration differed for specific five-year age groups.

Starting with the 1980 Census distribution of the population by single year of age, we flowed the population forward in time, adding actual births and subtracting the actual number of deaths by the specific age of the deceased as provided by the Lancaster County Health Department. The department had these data from 1987 to the present. For earlier years they provided us with information on deaths for 5-year age groups. Thus, we had to calculate the number of deaths for single years of age for 1980 to 1986 by establishing the percentage of deaths of specific 5-year age groups that occurred for each of the specific single-years during the 1987 to 1989 period. These percentages were applied to the number of deaths in each 5-year age group to establish how many deaths occurred for each single year of age.

We compared the values obtained via this flow to the estimates for the 1985 population of Lancaster County by age from the Census Bureau's population estimates program. The difference effectively gave us the amount of population change due to migration for each 5-year age group. The flow from the 1985 population estimates to the 1990 Census count gave additional amounts of migration for each 5-year age group. The levels were turned into rates of migration for each 5-year age group and then averaged to establish the 1980-1990 migration rates for each 5-year age group, which established the “low” series of migration. The same

process as just described was used with the 1990 census distribution by age flowed through to the 2000 Census to establish the “high” series of migration rates.

These migration rates were reviewed and some minor adjustments were made so that they fully represented intuitive sense. For example, the 1980s migration rates initially showed a small immigration for 5-9 year olds. However, outmigration had occurred for each 5-year age group from 25-29 year olds to 65-69 year olds (after adjustment) so it was unlikely children were arriving on net if their parents were net outmigrants. Thus, the migration rate for 5-9 year olds was adjusted to be a small outmigration. Another such intuitive adjustment was to take the small but widely fluctuating rates for those aged 85 and older and adjust them to be zero as little migration occurs among this demographic group.

The migration rates for 5-year age groups were then applied to single-year ages via a moving average approach. The 5-year rates were listed for each relevant single-year of age and then the average for a total of the 5-nearest years was calculated. Those 5-nearest years included that specific year of age along with the next two youngest and next two oldest years. This process smoothed the changes from one five-year rate to the next rather than having large jumps and gaps in the data. A migration rate for single-years of age was also necessary to be as accurate as possible in flowing the eventual projection model through from its Census 2000 starting point. The same process was used for calculating single year migration rates for each of the low, trend, and high-series models.

Migration rates for single years of college ages were aided by an analysis of the ratios for how the total population of one year compared to the next in Census 2000 data. The ratios established the level of migration needed to maintain the proper age structure for those of college age. In some instances, specific age ratios for 2000 appeared inconsistent with apparent trends – in such cases data for 1980 and 1990 were also utilized to determine an appropriate value. Without targeting these specific age-based migration rates, the total number of persons flowing through the model would not have matched the way it actually occurs. These efforts, while difficult, did improve the overall structure of the model for identifying how the college-age population changes as related to migration.

Age-Specific Birth Rates (for age of the mother)

Data were compiled on the number of Lancaster County births, the number of Lancaster County women by 5-year age groups from ages 15 to 44, and the corresponding birth rates for 5-year age groups from 1990 forward. These birth rates by 5-year age groups were then compared to corresponding values for the United States. Ratios of the Lancaster County rates to the U.S. rates were calculated for each 5-year age group. The ratios indicated that Lancaster County has a lower birth rate than the U.S. for women aged 15-19 and 20-24, and Lancaster County rates are higher for other age groups.

The ratios for 1990 and 2000 were relied upon more heavily to determine the overall values as they were based on more reliable statistics from the decennial Census. Estimates from non-census years can vary widely and are often revised, so the general trend since 2000 was noted and applied in conjunction was the rates from 1990 and 2000. The subsequent ratios were assumed to hold constant throughout the 2010 to 2040 projection time period. The ratios were

applied to national projections of birth rates calculated by CPAR to provide Lancaster County specific birth rates by age of mother in the projections period. The corresponding 5-year birth rates were applied equally to each single-year of age for mothers in that 5-year age group.

Age-Specific Survival Rates

The model used survival rates for single years of age to calculate the number of persons surviving from one year to the next. This provided the number of deaths by specific ages as well as the total number of deaths. Survival rates were taken from U.S. Census Bureau projection models.

When comparing the initial projections of deaths to those that actually occurred in Lancaster County in the post 2000 period, the model's number of deaths was too high. This was due to projected survival rates not accurately predicting the increased levels of survival attained recently with medical advances. Thus, in order to more accurately project deaths, survival rates for 15 years into the future were utilized at the starting point. In other words, when calculating deaths for the year 2000 in the model, the survival rates for 2015 were applied, for 2001 the survival rates for 2016 and so on. This formula gave the closest match of projected versus actual deaths in the 2000 to 2008 timeframe, for which actual vital statistics data were available. The model used the survival rates for Whites rather than the total population as Lancaster County demographics indicate that those in age groups most likely to become deceased (ages 75 and over) are predominately White. The minority population in Lancaster County is primarily younger than age 35, at least at the 2000 starting point of the projection. Only at the end of the projections period would the minority population move into the lower survival rate age groups of being aged 75 or older.

The projected survival rate data from the Census Bureau was listed for major years ending in 0 or 5 (2010, 2015, etc.) from 2000 to 2055. The changes in survival over 5 years for each single year of age were distributed evenly between the five years. Thus, the changes over each 5-year period were implemented evenly in a linear pattern to each individual year.

Flow through of population along with components of change

In order to project the population in 2010, the models started with the Census 2000 population distribution by single years of age. The age-specific survival rates and birth rates by age of mother were applied to this data. Additionally, the smoothed migration rates by single-year of age were also applied, effectively transitioning the population forward from 2000 to 2001. The process was repeated for each subsequent year.

Since factual data on vital statistics existed for the 2000 to 2008 timeframe, these values were compared to figures from the model. This comparison drove the decision to adjust the survival rate projection by 15 years as previously discussed. It also aided the final calls on the ratios between Lancaster County and U.S. birth rates for the various 5-year age groups of women of childbearing age.

Population estimates from the U.S. Census Bureau also illustrated how the model's total population values compared to those officially prepared by the bureau. Figures in the trend model were similar to the estimates as the Census Bureau has shown their data and models

indicate the level of migration in the post 2000 period has been similar to the trend level. However, a comparison of the 1990s estimates program to the final Census 2000 count indicated the Census Bureau underestimated the Lancaster County population by about 10,000 persons. Thus, we view that the 2010 Census headcount may be up to 10,000 above or below the current 2009 estimate. For that reason, the low and high series of population projections are presented, as well as to illustrate how the structure of the population would change under varying scenarios.

The low and high series of projections work under the assumption that the low and high rates of migration will be in effect for the latter part of the first decade (2005 to 2010) and then from 2010 to 2020. The models are held at the trend level from 2000 to 2005 as otherwise they are believed to present scenarios deviating too far from what is believed to have happened in the 2000s. Applying the high and low models' specific values from 2005 still shows how they diverge by 2010.

After 2020, the low and high models start a return to the trend level of migration. This was accomplished by adjusting the migration rates to represent 75 percent of the high or low series and 25 percent of the trend values during 2020 to 2030. Conversely, 25 percent of the high or low series and 75 percent of the trend series was applied during 2030 to 2040. This effectively scaled the high and low series rates back toward the trend rate. This assumption was viewed to more likely pattern reality than to keep the low and high migration rates constant decade after decade.

The number of deaths in each annual period was calculated as the inverse of the survival rate multiplied by the corresponding number of persons in that age group. For example, when a survival rate of a male 70-year old is say 0.975 then the death rate is one minus that value, or $1 - 0.975$ or 0.025. This means that 2.5 percent of those 70 year olds would become deceased prior to achieving their 71st birthday. Thus, multiplying 0.025 times the number of person age 70 at that time would give the corresponding number of deaths for 70 year-olds. Total deaths were calculated as the sum of the deaths by specific years of age.

Total births were identified in a similar fashion, with the exception that the birth rate was directly multiplied by the number of women of that age. Summing the number of births for women of each of the specific ages from 15 to 44 years gave the total number of births. While in reality births occur to mothers younger than age 15 and older than age 44, the rates, as calculated in these projections models utilizing a ratio of Lancaster County birthrates to the U.S. average, take into account these low levels of births at the age extremes so that the total number of births is accurate.

Birth and death rates remained the same in each projection model, regardless of the level of migration the specific model was using (low, trend, or high).

Net Migration and Domestic and International Components of Migration

In this analysis, net migration represented the residual value from subtracting natural change (births minus deaths) from the total population change. While age-specific migration rates were applied in the model, the easiest method to identify the level of net migration was through this residual method, as is often done for population change components within projections.

Detailed calculations regarding migration identified how much of the total net migration was from other domestic areas within the United States versus from international areas outside the U.S. The U.S. Census Bureau has made calculations for projecting the level of international immigration from 2010 to 2050. Their projections have a main model, a high series and a low series of international migration rates. The bureau's projections were relied upon to forecast international immigration in the local area.

Lancaster County and Nebraska have lower rates of international immigration than the U.S. as a whole. An analysis of post 2000 population estimates showed that Nebraska was attracting international residents at about 60 percent of the U.S. rate while Lancaster County did so at a pace of about 80 percent of the U.S. rate. Thus, while the U.S. rates had a high, low, and trend series, these rates were further adjusted to better represent international immigration to Lancaster County. For the trend series, the U.S. international immigration rates were multiplied by 80 percent to represent the typical level for Lancaster County. If international immigration is lower than trend nationally, so also will it likely be in Lancaster County, so the low series was multiplied by 60 percent, the typical level of Nebraska international immigration. The high series of migration for Lancaster County was left equivalent to the U.S. rate, since if international immigration was at a higher level nationally, so would it also be in Lancaster County. Under this approach, the high and the low series of international immigration specific to Lancaster County were an equivalent 20 percent above and below the trend level respectively.

The annual international immigration rates were multiplied by the total population to project the level of international immigration. International immigration rates for years prior to 2010 were held constant at a round value similar to the 2010 rate. Annual international immigration values were summed over five year periods and are presented in the tables to show the level of international immigration during each five years of the projection period. Domestic migration values were determined as the simple plug figure from subtracting the level of international immigration from the total level of net migration for each period.

Phase II – Household Projections

Determination of Household versus Group Quarters Population

All data for Phase II of the project was based upon the population projection using the trend level of migration. The population projection gave the total number of persons every 5 years from 2010 to 2040. To determine household statistics, the first item to be calculated was the percentage of population that actually lived in housing units, rather than group quarters housing (college dorms, nursing homes, prisons, etc.).

Historic information regarding the total population and the population in both households and group quarters was compiled, starting with the 1970 Census and utilizing each decennial census through 2000. Additionally information from the Census Bureau's newest data product, the American Community Survey (ACS), was compiled to provide an additional data point, namely the 2006-2008 timeframe. The data showed a slow increase in the percentage of the population residing in households from 1970 to 2000 before a small decline occurred in the 2006-08 data

(See Table 6). This decline is presumably due to the completion of new college dorms at the University of Nebraska-Lincoln and generally higher incarceration rates.

To project the percentage of the population in households into the future, values from Census 2000 for that variable by age were obtained. Then, those age-specific percentages of the total population that resided in households were lowered so that the total equaled the 94.6 percent the 2006-08 ACS showed. ACS tables provide the total number in households but do not break that data down for specific age groups. While all age group percentages were adjusted (increases in incarcerated population), the largest adjustments were made to college ages based on additional dorms known to have been built. The age 80 and over population also had a relatively large adjustment based on a likely greater need for and presence of nursing homes.

These percentages by age made to equal 94.6 for the full population when summed, were then applied to the projected populations by age from Phase I of the project to calculate the total number of persons living in households for each time period. The total population in households divided by the total projected population gave the total percentage that would be expected in households from the various population shifts. These data indicate a decline in the percentage of the population residing in households is expected as the population ages over time and the baby boom generation has an increased need for nursing homes (a group quarters style facility). The percentages as calculated were used directly in the model; no adjustments were made to smooth or otherwise modify these changes.

Average Household Size and Total Number of Households

Viewing historic census data from 1970 to the present 2006-2008 ACS showed a generally decreasing average household size. The average household size did remain the same between 2000 and 2006-08 at 2.40 persons per household (See Table 6). The average household size was projected into the future every 5 years between 2010 and 2040 utilizing these trends and published projections for other places like Sacramento, California, the state of Wisconsin, and the United States. The projection for Sacramento was relied upon more heavily as it represented another state capital for a city with similar age demographics.

The average household size in 2010 was held at the same level that the 2006-08 ACS showed as not much change was expected in the interim. From there, the average household size resumed its downward trend until it was projected to bottom at 2.34 persons per household in 2030. The average size rebounded a bit to 2.35 persons per unit in 2035 and 2040 as relatively more births occurred over this timeframe as the fourth wave stemming from the baby boom began. Grandchildren of baby boomers born in 2000 to 2010 would be entering their peak childbearing ages of 25-35 over this timespan, leading to relatively higher levels of births and the subsequent slightly higher average household size.

The total number of households was then calculated via the simple formula of dividing the total population living in households by the average household size.

Distribution of Households by Age of the Householder

We again compiled the number of households by age of the householder historically from 1970 to the present 2006-08 timeframe. Census data by age of the householder have categories with

householders as young as 15 years old. The figures were turned into percentage distributions by age of the householder and then compared to the percentage of the population in those same age groups for the same population aged 15 and older. Dividing the two percentage distributions provided a ratio of relatively how much of a certain age group were in fact householders.

Plugging in the projected populations by age from the trend model and applying the ratios calculated led to the figures for householders by age. We applied the ratio obtained from the 2006-08 data for the nearby 2010 point in time, and then the average ratios from the last three historic datapoints (1990 and 2000 Censuses along with 2006-08 ACS) for 2015 to 2040. How this ratio would change into the future would be speculative at best, so it was held constant for the majority of the projection.

Calculation of the Number and Percentage of 1-Person Households

While historic data for Lancaster County was only available since 1990, it has shown that the percentage of households that have only one resident has been increasing. The number of 1-person households by age of the householder was available for 1990 and 2000 but not for all ages from the detailed tables of the 2006-08 ACS. Thus, we custom calculated those values using the 2006-08 Public Use Microdata Samples (PUMS) provided by the Census Bureau.

The PUMS are designed so that researchers can calculate custom tables. They show the raw data to a select subsample of the actual survey responses obtained in the ACS. Weights are provided in the file so that the sample represents the entire population.

Any PUMS analysis must be based on an adequate number of cases in the file. In this analysis we felt that Lancaster County alone had too few cases on which to base such an analysis so we added Douglas County cases in as well. Both counties had similar percentages of 1-person households by age group in 2000, with Douglas County tending to have a slightly higher percentage for most groups.

The PUMS analysis showed changes in 1-person households well for younger age groups. Given the limited number of cases among older age groups, the PUMS analysis gave what in our view were some figures that had certain quirks and low reliability. American Factfinder tables from the Census Bureau did specifically show 1-person households for householders age 55 and older. Thus, values and changes since 2000 for the U.S. were used for these older age groups.

Data for age groups younger than 55 starting in 2010 was determined as the calculated level for 2006-08 for Douglas and Lancaster Counties minus the small differential that existed between the two counties in 2000. This effectively provided the percentages of 1-person households by age for Lancaster County in the 2006-08 timeframe. These values were applied to the 2010 point in time as they were viewed to not have changed in the interim.

Changes between 2000 and 2006-08 for Lancaster County were annualized and applied over five years to get the percentage of households that had one resident for each age group in 2015. Thus, the full change witnessed by the trend in increasing levels of 1-person household per age group of the household was applied between 2010 and 2015. In our view this trend would not continue at a linear rate as changes in an item increasing year-over-year tend to slow over time. Thus, the

full change was scaled by to 80, 60, 40, and 20 percent of the full change over the 2020 to 2035 timeframe. The 2040 value was held at the 2035 level.

These projected percentages of one-person households by age of the householder were applied to the calculated number of total households by age of the householder. When summed, these calculations gave the total number of 1-person households and simple division into the total number of households gave the projected percentage of 1-person households from 2010 to 2040.

Nonfamily and Family Households along with Family Households with Children

With the percentages of 1-person households calculated as described above, the percentage of nonfamily and family households could then be projected. Households that have only 1 resident are nonfamily households by definition. Historic data was analyzed to view the amount and change in other nonfamily households (roommates, unmarried partners, etc.).

The historic analysis showed that other non-family households had increased an average of 0.12 percentage points per year or 0.60 percentage points over 5 years. The 2006-08 ACS showed the percentage of nonfamily households was 33.4 percent, of which 29.2 percent were one-person households and the remaining 4.2 percent were other nonfamily households. The increase in other nonfamily households was expected to continue. Since the 2006-08 ACS data can be viewed as centered around calendar year 2007, the percentage of other nonfamily households in 2010 was calculated by multiplying the 0.12 average annual increase by 3 years (.36) and adding it to the 4.2 percent from the 2006-08 timeframe to equal 4.6 (as rounded to the nearest tenth). The aforementioned 0.60 percentage point increase was added linearly for each 5-year period in the projection timeframe until 2040.

With these percentages of other nonfamily households and the calculated percentages of 1-person households from earlier stages of the projection, the total percentage of nonfamily households was found via simple addition. These percentages of nonfamily households were multiplied by the total number of households to determine the overall number of nonfamily households. The number of family households was determined by subtracting the number of nonfamily households from the total number of households.

The percentage of families with children under 18 years of age was analyzed historically for both Lancaster County and the U.S. The percentage of family households that had children under 18 has remained remarkably stable in Lancaster County since 1980, with about 50 percent of family households having a child under age 18. Nationally, the percentage has declined slightly. Based on these factors, the Lancaster County percentage of family households with kids was projected to decrease slightly over the projection period, near the rate of the average decline nationally. The starting value was based on the average values of preceding time points in Lancaster County. Multiplying these percentages by the total number of family households provided the number of family households that were projected to have children under 18 at future points in time.
